## Introduction

The Tanner crab assessment model currently uses the multinomial probability distribution to describe the likelihood associated with size composition data from the EBS shelf survey (Stockhausen, 2021). The precision or, in contrast, the uncertainty, associated with a sampled multinomial distribution is characterized by the sample size: the higher the sample size, the more precisely an observed size composition reflects the true composition. When the population being observed is sampled in a truly random fashion, so each individual in the population has an equal chance of being sampled, the sample size is equal to the number of samples taken (i.e., individuals measured). However, because crab (and groundfish) in the EBS are patchily distributed in groups of similar size, the assumption of random sampling is violated in the EBS shelf survey and the number of crab measured in the survey overestimates the precision of the resulting size compositions. In trawl surveys like the EBS shelf survey, in which a population is sampled in a two-step process by taking a number of hauls distributed across the range of the population, with size (and other biological characteristics such as sex, maturity state, and shell condition) measurements taken on a number of individuals caught in each haul, the "true" sample size that reflects the precision/uncertainty of the observed size composition typically varies between the total number of animals measured and the number of hauls in which animals were captured and measured (hauls in which no animals were captured and measured are important in determining the extent and size of the population being sampled, but contribute nothing to understanding the distribution of sizes within the population). For Tanner crab, then, the "true" sample sizes for annual size compositions from the EBS shelf survey can range
between 10's-100's (hauls at which crab were found and measured) and 1,000 's (numbers of crab measured), depending on sex, maturity state, and shell condition.

Because the Tanner crab is an integrated assessment model that seeks to balance model fits to data across a variety of data types and sources (e.g., indexes of abundance and biomass, survey and fishery size compositions, growth and maturity data) in order to estimate underlying parameters governing population dynamics, reflecting fishery prosecution, and addressing management issues such as sustainable yield, it is important to accurately characterize the precision/uncertainty associated with the those data. The relative weights assigned to different data sources in the parameter estimation algorithm can influence the values of the estimated parameters, particularly when different data sources encompass conflicting information. The Tanner crab model uses a maximum likelihood approach to parameter estimation with input sample sizes for survey size compositions fixed at 200 per sex in all years, where the value of 200 reflects a practical choice for the assumed precision of the size compositions that allows the estimation algorithm to converge. In past work to improve on using a fixed sample size when fitting the model, several iterative re-weighting schemes were tried but did not produce reasonable results. The Dirichlet-Multinomial distribution (Thorson et al. 2016), as a substitute for the multinomial, allows for the estimation of the "effective" sample size as a parameter with the input sample size as an upper bound. Application of this distribution in previous models resulted in the "effective" sample size being estimated as the same as the input sample size, suggesting the default input sample size of 200 may not be a bad practical choice.

To investigate this issue more thoroughly, a "bootstrapping" technique (Stewart and Hamel, 2014) was applied to EBS survey data to estimate annual input sample sizes for survey size compositions for male Tanner crab, as well as immature and mature females. The resulting bootstrapped sample sizes were then used as input sample sizes to re-fit the 2021 assessment model (referred to here as 22.02 ) and compare changes in results with the original (21.22a).

## Bootstrapping

Two-stage bootstrapping as described in Stewart and Hamel (2014; hauls within survey strata, individuals within hauls) was applied to Tanner crab EBS survey data on an annual basis for the entire survey dataset (1975-2021) to derive effective sample sizes for male, immature female, and mature female size compositions (Tables 1, 2; Figures 1-4). The average number of males measured in the survey was 6292 , while the average number of stations at which crab were found was 215. The arithmetic mean effective N was 394 , while the average harmonic mean effective N was 266. The average (across all years) relative reduction from the measured number of males to the harmonic mean effective $\mathrm{N}\left(N_{\text {measured }} / N_{\text {harmonic }}\right)$ was 96 . For immature females, the average number measured in the survey was 2300 , while the average number of stations at which crab were found was 215 . The arithmetic mean effective N was 145 and the average harmonic mean effective N was 266 , while the average relative reduction from the measured number of immature females to the harmonic mean effective N was 96 . The average number of mature females measured in the survey was 1698 , while the average number of stations at which crab were found was 126 , the arithmetic mean effective N was 234 , and the average harmonic mean effective N was 129 . The average relative reduction from the measured number of mature females to the harmonic mean effective N was 92 .

Stewart and Hamel (2014) examined several estimators for bootstrapped effective N's and found the harmonic mean to have the least bias ( $<1 \%$ ) and subsequently recommended its use. The average harmonic mean effective N 's over the survey time series ( 82 for males, 395 for females) agreed surprisingly well with the default value of 200 used to fit sex-specific survey size compositions in the
assessment model. However, the harmonic effective mean varies appreciably (on the order of $30 \%$ ) over the time series (as do the arithmetic average effective N , the number of non-zero hauls, and the numbers measured), so using annual values of the harmonic mean effective N as input sample sizes for survey size composition data in the assessment model may better reflect the associated variability in precision (or uncertainty, conversely) of the data compared with using a fixed value.
