# Stock assessment for eastern Bering Sea Walleye Pollock: some preliminary alternative evaluations based on external review 

James Ianelli<br>Alaska Fisheries Science Center, NOAA

## Abstract <br> Introduction

Three independent experts reviewed the stock assessment for eastern Bering Sea Walleye Pollock in May 2016. The terms of reference and presentations and their subsequent reports can be found at: www.tinyurl.com/pollockCIE2016. Several improvements to the assessment were recommended and those seen as highest priority that could be reasonably addressed this year include:

1. Modify the body weight-at-age estimation method to be based on increment rather than expected values
2. Fit the model to biomass indices rather than total population numbers
3. For the acoustic trawl data, use the time series that covers the water column down to a half meter from bottom rather than down to 3 meters from bottom.
4. Evaluate data weightings from first principles for input sample sizes
5. Evaluate whether weightings are appropriate given model fit
6. Consider components of variability of the $F_{m s y}$ estimation and the effect of the prior

The following sections are intended as a start to begin addressing these concerns.

## 1. Body weight-at-age estimation

Modern stock assessment methods that lead to scientific advice on sustainable fishing practices typically revolves around ensuring that fishing mortality rates are at or below values used as reference points. In most management settings, conservation measures are set based on catch biomass limits with some assumption about expected body mass-at-age (hereafter referred to as weight-at-age) to convert from modeled catch numbers (as specified based on the fishing mortality rates). Uncertainty estimates are typically concerned with the absolute values of the population numbers-at-age estimates and the stock productivity estimates leading to acceptable fishing mortality reference points. While uncertainty from these sources is obviously important for evaluating risks in management settings, the additional uncertainty due to unknown weight-at-age is typically ignored (Jaworski 2011)

For many fisheries settings empirical estimates of mean body mass-at-age are quite precise due to sampling design and effort. For example, the uncertainty of estimated mean body mass for the eastern Bering Sea (EBS) walleye pollock (Gadus chalcogrammus) for the main fished ages typically has coefficients of variation below $5 \%$.

The model for predicting mean body weight-at-age in the fishery has two purposes, prediction of the current and future year values and their relative uncertainty. As shown in section 5 below, the uncertainty in average weight estimation is an important component.

## Data

Fishery sampling for EBS pollock is extensive with large numbers of age, weight, and length measures sampled from the catch each year (Tables 1 and 2). NMFS observer sampling data on catch-at-length and age composition was estimated using the methods described by Kimura (1989) and modified by Dorn
(1992). Length-stratified age data are used to construct age-length keys for each stratum and sex. These keys are then applied to randomly sampled catch length frequency data. The stratum-specific age composition estimates are then weighted by the catch within each stratum to arrive at an overall age composition for each year. Data were collected through shore-side sampling and at-sea observers. The three strata for the EBS were: i) January-June (all areas, but mainly east of $170^{\circ} \mathrm{W}$ ); ii) INPFC area 51 (east of $170^{\circ} \mathrm{W}$ ) from July-December; and iii) INPFC area 52 (west of $170^{\circ} \mathrm{W}$ ) from July-December. This method was used to derive the age compositions from 1991-2015 (the period for which all the necessary information is readily available).

The catch-at-age estimation method uses a two-stage bootstrap re-sampling of the data. Observed tows were first selected with replacement, followed by re-sampling actual lengths and age specimens given those sets of tows. This method allows an objective way to specify the effective sample size for fitting fishery age composition data within the assessment model. In addition, estimates of stratum-specific fishery mean weights-at-age (and variances) are provided which are useful for evaluating general patterns in growth and growth variability. For example, Ianelli et al. (2007) showed that seasonal aspects of pollock condition factor that could affect estimates of mean weight-at-age vary substantially within years. In 2016, the routine for estimating weights-at-age was updated to be adaptable to other stocks and converted into an R package. The values were re-computed for the period 1991-2014 (and include 2015) and estimated mean body weights-at-age were nearly identical to those previously used (Fig. 1). A detailed summary of the relative mean weight-at-age estimates is shown in a series of figures presented in Appendix 1.

As part of the response to the CIE review completed in May 2016, these calculation updates also included some new estimation methods including Francis (2011) method for estimating input effective sample sizes. This was done by the simple method as: $N_{y}=v_{y} / V_{j}\left(\bar{A}_{j z}\right)$, where $\bar{A}_{j y}$ is the mean age of the $j^{\text {th }}$ bootstrap in year $y, V_{i}$ is the variance over the bootstrap samples, $v_{y}$, the variance of the observed composition in year $y$ is calculated as $v_{y}=\sum_{i} a^{2} p_{a y}-\left(\sum_{a} a p_{a y}\right)^{2}$ and $p_{a y}$ is the proportion-at-age $a$ in year $y$. Results applying this method suggest that the effective input sample sizes range from about 2 thousand to over 12 thousand fish (Table 3).

## Models

The growth model followed the parameterization of Schnute and Fournier (1980), with the addition of cohort effects and annual year effects:

$$
\begin{array}{ll}
\hat{w}_{i j}=\mu_{j} e^{\delta_{i}} & j=1, \\
\hat{w}_{i j}=\hat{w}_{i-1, j-1}+\Delta e^{\zeta_{i}} & j>1, \\
\Delta_{j}=\mu_{j 1}-\mu_{j} & j<1  \tag{1}\\
\mu_{j}=\alpha\left[L_{1}+\left(L_{2}-L_{1}\right)\left(\frac{1-K^{j-1}}{1-K^{j 1}}\right)\right]^{3}
\end{array}
$$

with symbols defined in Table 4. The years and ages for model application can be specified independently of the data extent. As with Jaworski (2011) a series of prediction methods were evaluated against a measure of predictive performance. These alternative estimators for mean weight-at-age were developed based on evaluating a variety of potentially useful independent variables. Potential explanatory variables were evaluated provided that they would be available at the time of the assessment in each year (e.g., since the bottom trawl survey is used to collect temperature information, this may be useful to predict
mean weights in the fishery). The objective function used to evaluate estimator performance was simply examining how well "out-of-sample" data were predicted. For example, for a particular estimator, the first iteration data from 1991-2000 were used to estimate the mean weights in 2001 and 2002. These estimated were then compared to the actual mean weights observed for 2001 and 2002. The second iteration repeated this process but used data from 1991-2001 to estimate 2002 and 2003 data for comparison with actual observations. This sequence was continued through to using data from 1991-2014 to estimate 2015 means (and compared with actual 2015 mean values). Since some age-groups are relatively more important than others to the fishery (in terms of prediction errors), comparisons of estimates with "observed" were weighted by the relative importance of different age-groups. The relative importance of different age-groups was computed by using the mean numbers-at-age estimated in the population from Ianelli et al. (2015) and accounting for the fishery selectivity and mean weight over that period. This weighting scheme is intended to favor estimators for age-groups that are most important to the fishery and is computed as:

$$
\gamma_{u}=\frac{\bar{N}_{a} s_{u} \bar{w}_{a}}{\sum \bar{N}_{u} s_{u} \bar{w}_{u}} .
$$

Then the estimator that performed best minimizes:
$\sum_{y-2006}^{2015} \sum_{l-y, y}^{y 11} \sum_{a-3}^{15} \gamma_{a}\left(w_{t, a}^{\prime}-\hat{u}_{t, a}^{k}\right)^{2}$ where $y$ is the "assessment" year, $\hat{w}_{t, 4}^{k}$ is the $\mathrm{k}^{\text {th }}$ estimator for mean weight-atage $a$, in year $y$, and $w_{t, a}^{\prime}$ are the actual observations in year $t$. The vector for the $g_{a}$ weighting was based on estimates from 2000-2015:

| 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| 0.031 | 0.132 | 0.227 | 0.222 | 0.155 | 0.089 | 0.055 | 0.033 | 0.022 | 0.014 | 0.009 | 0.005 | 0.006 |

## Parameter estimation

The estimation configurations tested included simple means to more complex year- and cohort- specific random effects approaches (Table 5) and was coded in both TMB (Kristensen et al., 2016) and ADMB (Fournier et al., 2012). The code used is available at http://goo.gl/h8So5Z .

## Results

The projection model for the mean weights-at-age in retrospective fitting shows the high level of variability and relatively poor skill in model predictions (Fig. 2). Nonetheless, the performance was substantially improved with the inclusion of current year survey data and modeling the cohort and year effects (Fig. 3). A preliminary evaluation of observed factors that might affect growth changes was also conducted. Temperature anomalies appeared to have a poor relationship with growth increment year effects (Fig. 4).

Table 1. Numbers of pollock fishery samples measured for lengths and for length-weight by sex and strata, 1977-2015, as sampled by the NMFS observer program.

Table 4. Equations and model parameters

| Symbol | Descripion |
| :---: | :---: |
| $\hat{w}_{i j}=\mu_{j} e^{\delta_{i}} \quad j=1, \quad i \geq 1$ | Growth model |
| $\hat{w}_{i j}=\hat{w}_{i-1, j-1}+\Delta e^{\zeta_{i}} \quad j>1, \quad i>1$ |  |
| $\Delta_{j}=\mu_{j 1}-\mu_{j} \quad j<J$ |  |
| $\mu_{j}=\alpha\left[L_{1}+\left(L_{2}-L_{1}\right)\left(\frac{1-K^{j-1}}{1-K^{j}}\right)\right]^{3}$ |  |
| $\hat{w}_{i j}$ | Expected mean weight-at-age $j$ in year $i$ |
| $i, j$ | Index for year and age |
| $\mu_{j}$ | Mean length age $j$ |
| $\Delta_{j}$ | Mean growth increment |
| $\alpha$ | Constant to scale lengths |
| $\delta_{i} \zeta_{i}$ | Cohort and year effects |
| $K, L_{1}$, and $L_{2}$ | Parameters of the von Bertalanffy growth |

Table 5. Alternative methods evaluated for computing mean weight-at-age for EBS pollock.

| Method | Description |
| :--- | :--- |
| Means | Mean fishery weights-at-age of most recent $n$ years of data $(n=1,3,5$, and 10) |
| Year and Cohort | Year and cohort effect model |
| Year and Cohort <br> with scaled survey data <br> Year effect only <br> (with scaled survey data) | Include scaled survey weights-at-age ( $\left.\hat{w}_{i, j}^{k-2}=\lambda_{j} w_{i, j}^{\text {sureter }}\right)$ |
|  | Year effect model (a random effect parameter for each annual growth increment) |

Figure 1. Comparisons of average fishery weight-at-age (kg) for EBS pollock, 1991-2015 from the 2015 assessment and the current revised estimates.

Figure 2. Projection results compared to data for fishery weights-at-ages 4-7. The lines represent estimates set equal to the most recent value for the current assessment year and next year whereas the solid bullets and triangles represent the modeled estimates for the current assessment year and next year, respectively. The stars represent the final realized estimates based on the observer data.

Figure 3. Scores of performance for different methods for projecting average body weight where projection year of 0 means current (assessment) year and 1 means the coming year used for $\operatorname{ABC}$ estimation. Models labeled $1,3,5$, and 10 represent the means over that many most recent years. The right-most "Models" are random effects approaches with and without survey data included.

Figure 4. Estimated year effect on growth increment compared to Bering Sea temperature anomaly for EBS pollock.

## 2. and 3. Tuning model to survey biomass indices instead of numbers and alternative AT data

In the original development of the model, the option to tune to survey estimates of population numbers or biomass was available. The tradition of tuning this model using numbers should be re-evaluated. As such the following models were defined for incremental evaluations:

Model Description
Model 0.0 The 2015 model used for management advice
Model $0 \quad$ As Model 0.0 but using the design-based trawl survey estimates (and likelihoods) instead of the Kotwicki index

Model 1 As Model 0 but tuned to acoustic survey biomass instead of AT numbers
Model 2 As Model 0 but tuned to bottom trawl survey biomass instead of bottom trawl survey numbers

Model 3 As Model 0 but tuned to both acoustic and bottom trawl survey biomass estimates instead of numbers

Model 4 As Model 3 but using the acoustic trawl survey data covering the water column extended to 0.5 m from bottom instead of the traditional 3 m .

Note that model 0 was modified slightly from 0.0 to make for a clearer comparison of impacts of changes in subsequent models. The estimates from Lautenberger et al. (in press) extend the acoustic-trawl data from the near surface down to 0.5 m from the bottom. Generally, the trends are similar to the values which extended only down to 3.0 m (Table 6). These results suggest that, on average, about $26 \%$ of the acoustic backscatter attributed to pollock occurs between 0.5 and 3.0 m . As noted above, the biomass estimates for these comparisons are based on standard design-based estimates from the bottom trawl survey (instead of the "Kotwicki index") so that consistent model comparisons were possible.

Table 6. Acoustic trawl survey biomass estimates for EBS pollock based on the methods of Lauthenberg et al. (in press) for different segments of the water column.

| $\sim$ | 15m - 3 m <br> estimates | Water column to <br> 0.5 | $0.5-3 \mathrm{~m}$ <br> estimates | Proportion increase <br> from 3 m estimates |
| ---: | ---: | ---: | ---: | ---: |
| 1994 | $2,886,235$ | $3,640,106$ | 753,871 | $26 \%$ |
| 1995 |  |  |  |  |
| 1996 | $2,310,742$ | $2,955,115$ | 644,373 | $28 \%$ |
| 1997 | $2,590,929$ | $3,590,695$ | 999,766 | $39 \%$ |
| 1998 |  |  |  |  |
| 1999 | $3,344,679$ | $4,202,143$ | 857,464 | $26 \%$ |
| 2000 | $3,048,718$ | $3,613,940$ | 565,222 | $19 \%$ |
| 2001 |  |  |  |  |
| 2002 | $3,622,070$ | $4,330,008$ | 707,938 | $20 \%$ |
| 2003 |  |  |  |  |
| 2004 | $3,306,937$ | $4,016,180$ | 709,243 | $21 \%$ |
| 2005 |  |  |  |  |
| 2006 | $1,560,174$ | $1,887,421$ | 327,247 | $21 \%$ |
| 2007 | $1,769,019$ | $2,288,070$ | 519,051 | $29 \%$ |
| 2008 | 996,939 | $1,407,479$ | 410,540 | $43 \%$ |
| 2009 | 923,843 | $1,323,060$ | 399,217 | $14 \%$ |
| 2010 | $2,322,643$ | $2,651,176$ | 328,533 | $25 \%$ |
| 2011 |  |  |  |  |
| 2012 | $1,842,792$ | $2,298,941$ | 456,149 |  |
| 2013 |  |  |  |  |
| 2014 | $3,438,986$ | $4,726,599$ | $1,287,613$ |  |

## Results

Some patterns emerged between model alternatives using survey numbers in place of biomass estimates in the model fitting process. For the bottom trawl survey, model fits to abundances when biomass was tuned (Models 2-4) and tended to show negative residuals, whereas in models 0 and 1 (when bottom trawl survey abundances were used for tuning), the residuals for biomass fits were mostly positive (Fig. 5). For the acoustic trawl survey data, model fits were generally reasonable for numbers and biomass, regardless of which one was actually used in the tuning (Fig. 6). The different model configurations resulted in minor changes to spawning biomass estimates (Fig. 7). Models 3 and 4 appear to have a slightly lower estimates overall.

Figure 5. Model fits to design-based bottom trawl survey estimates for abundance (top set of panels) and biomass (bottom set) for EBS pollock based on the 2015 model configuration.

Figure 6. Model fits to acoustic trawl survey estimates for abundance (top set of panels) and biomass (bottom set) for EBS pollock based on the 2015 model configuration.

Figure 7. Model fits to acoustic trawl survey estimates for abundance (top set of panels) and biomass (bottom set) for EBS pollock based on the 2015 model configuration.

## 4. Evaluate whether weightings are appropriate given model fit

Part of the work on this consisted of developing statistics for the CIE panel during the review.

## 5. Consider components of variability of the $F_{m s y}$ estimation and the effect of the prior

The reviews note a number of concerns regarding the pdf of $F_{m s y}$ estimate. In an effort to clarify which sources of variability can contribute to the pdf a set of alternatives were developed as follows:

Model Description
Model $0 \quad$ The 2015 model used for management advice
Model 1 Fix mean weight-at-age (instead of propagating process-error uncertainty)
Model 2 Fix selectivity to mean
Model 3 Fix both selectivity and mean weight
Model 4 Set steepness to have prior variance alone (omit influence of "data")

Note that the point of developing these models was to evaluate how the pdf of $F_{\text {msy }}$ changes due to different model specifications. In particular, Model 4 could be viewed as an extreme case of uncertainty since this configuration assumes the only information on steepness comes from "expert advice" based on the prior distribution specified.
